ABSTRACT

Both in Europe and worldwide cheese has caused important outbreaks of listeriosis and can be a vehicle for transmission of *Listeria monocytogenes* to consumers. A systematic review and meta-analysis were conducted using scientific literature and European Food Safety Authority (EFSA) reports to summarize available data on the prevalence of *L. monocytogenes* in different types of cheeses produced in Europe. Meta-analysis models were used to estimate mean prevalence of the pathogen and to compare prevalence among types of cheeses (fresh, ripened, veined, smear and brined) and cheeses produced using, respectively, pasteurized or un-pasteurized milk. Data from a total of 130,604 samples were analysed. Mean prevalence for presence during 2005-2015 estimated from scientific literature (2.3% with confidence interval (CI): 1.4-3.8%) was more than three times higher than results from EFSA reports (0.7%; CI: 0.5-1.1%). The prevalence differed among types of cheeses including fresh (0.8%; CI: 0.3-1.9%), ripened (2.0%; CI: 0.8-4.9%), veined (2.4%; CI: 0.9-6.3%), smear (5.1%; CI: 1.9-13.1%) and brined (11.8%; CI: 3.5-33.3%). Mean prevalence of *L. monocytogenes* in soft/semi-soft cheeses were not significantly different ($P > 0.05$) for cheeses produced from pasteurized (0.9%; CI: 0.4-1.9%) or un-pasteurized (1.0%; CI: 0.4-2.2%) milk. For cheese samples reported by EFSA 0.2% CI: 0.1-0.4% had concentration of *L. monocytogenes* above the critical European limits of 100 cfu/g. In addition, this systematic review focused on groups/species of microorganisms suitable as indicator organisms for *L. monocytogenes* in cheeses to reflect the level of production hygiene or as index organisms to assess the prevalence of *L. monocytogenes* in cheeses. However, no suitable indicator or index organisms were identified. The performed meta-analyses improved our understanding of *L. monocytogenes* prevalence in different types of cheeses and provided results that can be useful as input for quantitative microbiological risk assessment modelling.

Keywords: Occurrence, fresh cheese, soft and semi-soft cheeses, risk assessment

1. Introduction

The genus *Listeria* includes more than 20 species that can be divided into three clades (Weller et al. 2015). Two *Listeria* species belonging to the same clade are generally considered to be pathogenic, *L. monocytogenes* in humans and *L. ivanovii* in other mammals. Nevertheless, there have been some reports of *L. seeligeri* and *L. ivanovii* causing illness in humans (Cummins et al., 1994; Rocourt et al., 1986). The likelihood of *L. monocytogenes* infection leading to listeriosis is greatest among certain groups; including pregnant woman, neonates, immunocompromised adults and the elderly (Ryser & Marth, 2007). Within the European Union (EU) there has been a statistically significant increasing trend of listeriosis over the period 2009-2015. Specifically, the numbers of confirmed human cases of listeriosis were 1,331 and 2,206 in 2009 and 2015, respectively (EFSA, 2016). A total of 270 deaths due to listeriosis were reported within nineteen EU member states. The overall EU notification rate of listeriosis was 0.46 cases per 100.000 population with a case-fatality rate of 17.7% (EFSA, 2016). Seven EU Member States and Norway provided information from conventional serotyping of *L. monocytogenes* (accounting for 23.3 % of all confirmed cases). The most common serotypes in 2013 were 1/2a (57.5 %) and 4b (34.3 %), followed by 1/2b (6.4 %), 1/2c (1.4 %), 3a and 3b (both 0.2 %) (EFSA, 2015).

In 2010-2011 an EU baseline survey (EFSA, 2013a) collected data about presence of *L. monocytogenes* and the non-compliance for different ready-to-eat (RTE) food categories at retail. The proportion of *L. monocytogenes* positive samples at retail was highest in fish products (mainly smoked fish), followed by soft and semi-soft cheeses and RTE meat products. Specifically, the EU prevalence of *L. monocytogenes* in cheeses at retail was 0.47 % (CI: 0.29-0.77%) determined as 16 positive samples out of 3393 at the end of shelf-life. For these 2010-2011 samples 0.06% (CI: 0.02-0.24 %) determined as two samples out of 3393 exceeded the critical concentration of 100 cfu/g

67 (EFSA, 2013a). In 2015 fifteen samples out of 3039 exceeded the critical concentration of 100 cfu/g
68 (EFSA, 2016).

69 The first reported outbreak of human listeriosis associated with consumption of cheese
70 occurred in the USA during 1985 (Linnan *et al.,* 1988) and was caused by a fresh cheese. Since
71 then, several outbreaks associated with consumption of cheese have occurred worldwide and
72 fatalities continue to be reported (Table 1). Clearly, it is important to collect information and to
73 analyse data in an attempt to improve our understanding and options to better manage this risk.

74 Meta-analysis is a statistical approach that can be used to analyse, for example, prevalence data
75 (effect size) originating from various sources (primary studies) and in this way provide an overview
76 of effects and variability (Glass, 1976; Sutton, et al., 2001). Lately, meta-analysis has been used to
77 study several food safety issues and the quantitative results obtained can been used as inputs in risk
78 assessment models (Baron et al., 2009).

79 Fortunately, prevalence and concentrations of *L. monocytogenes* in cheeses and cheese
80 processing environments are low. Therefore, to evaluate its potential presence other index or
81 indicator microorganisms that are easier to determine or quantify can be relevant to analyse. Index
82 organisms can be used to assess likelihood of the presence of a pathogen whereas indicator
83 organisms demonstrate a failure in Good Hygiene Practices (GHP) (Brodsky, 1995; Mossel, 1978).
84 EU Regulation (EC) No 2073/2005 use coagulase-positive staphylococci as index organisms to
85 assess the likelihood of staphylococcal enterotoxins in cheese made from raw or pasteurized milk
86 and *E. coli* is used as an indicator for the level of production hygiene in cheese made from milk that
87 has undergone heat treatment. Furthermore, *Listeria* spp. has been used as index organisms for the
88 likely presence of *L. monocytogenes* in food (FSIS, 2014; Gilbert et al., 2000).

89 The objective of the present study was to perform a systematic review and a meta-analysis
90 of the prevalence of *L. monocytogenes* in different types of European cheeses and study potential
91 indicator organisms for assessment of production hygiene or index organisms for implementation in
92 the assessment of product safety.

93

94 **2. Materials and methods**

95 *2.1. Literature search and inclusion criteria*

96 A systematic review was performed following the protocol presented by Sargeant et al.,
97 2005. Literature searches were carried out to identify suitable scientific literature using Web of
98 Science (2017) or DTU Findit (2017) databases for papers indexed since 1985 as well as Google
99 searches using English, French, Italian, and Spanish terms for combinations of *Listeria* spp., *L.*
100 *monocytogenes*, cheese, dairy, prevalence, incidence and occurrence. Electronic searches were
101 carried out to identify reports of the prevalence for *Listeria* spp. in cheese. This included reports by
102 national and international organizations such as World Health Organization (WHO), EFSA and the
103 International Commission for Microbiological Specification in Foods (ICMSF).

104 For inclusion in the meta-analysis results had to meet three requirements: (i) to come from
105 original studies, (ii) to be obtained by using approved (FDA/FIL-IDF or ISO) microbiological
106 methods for detection of *Listeria* spp. and (iii) originate from cheeses produced in Europe during
107 the period of 2005 to 2015.

108 *2.2. Data and definitions*

109 Cheese-type definitions were necessary in order to categorize studies from scientific
110 literature. Available information allowed for a classification based in maturation characteristics. For

111 the purpose of this paper, the following definitions apply. Fresh cheeses are curd-style cheeses
112 which do not undergo any ripening (CAC, 2013), for example, queso fresco, cottage cheese,
113 Mozzarella or Ricotta. Ripened cheeses are not ready for consumption shortly after manufacture
114 and maturation is needed for development of specific cheese characteristics (CAC, 2013), for
115 example, Gouda, Edam, Cheddar or Parmesan. Veined cheeses are ripened cheeses in which
116 ripening has been accomplished primarily by the development of the mould *Penicillum roqueforti*
117 throughout the interior and/or on the surface, for example, Roquefort, Gorgonzola, Cabrales, Stilton
118 or Danablu. Smear cheeses are ripened cheeses where the surface is treated with *Penicillum*
119 *candidum, Penicillum camemberti* or *Brevibacterium linens*, for example, Brie, Camembert,
120 Limburger or Taleggio. Brined cheeses are ripened and stored in brine until they are sold or packed,
121 for example, Feta or Ricotta salata (Fox et al., 2000).

122 Classification of cheese in EFSA reports are based on cheese moisture content. Soft-cheeses
123 have a percentage of moisture, on a fat-free basis, higher than 67 %. Semi-soft cheeses have 62 to
124 67 % fat-free moisture and are characterized by their firm but elastic feel. Hard cheeses have 49 to
125 56 % fat-free moisture (CAC, 2013; EFSA, 2013b).

126 *2.3. Problem statement*

127 To estimate prevalence of *L. monocytogenes* in cheese during the period 2005-2015 (i) from
128 scientific literature data, (ii) from data in EFSA reports, (iii) from scientific literature and data in
129 EFSA reports when combined and (iv) to study groups/species of microorganisms suitable as
130 indicator or index organisms to assess prevalence of *L. monocytogenes* in cheeses.

131 *2.4. Description of data sets for meta-analysis and regression modelling*

132 From each primary study the number of samples positive for *L. monocytogenes* (s) and the
133 total number of samples (n) were extracted. Information about year of survey, country, sample

134 weight and information on sampling at production site or at retail were also collected from each
135 primary study. Meta-analysis for prevalence of *L. monocytogenes* in cheese as reported in the
136 scientific literature was based on 17 primary studies including a total of 7,221 samples (Table 2),
137 while data from seven EFSA reports with a total of 123,383 samples were included (Table 3 and
138 Table 4). The regression model used to evaluate indicator/index organisms for *L. monocytogenes* in
139 European cheeses was based in 16 primary studies all from the scientific literature and including a
140 total of 3,852 samples (Table 5).

141 *2.5. Meta-analysis*

142 Prevalence $\left(p_i = {}^{s_i}\!/_{n_i}\right)$ data was studied as observed effect size (θ_i) and they were logit
143 transformed in order to restrict values to a range between 0-1 and to stabilize variance (Eq. 1;
144 Viechtbauer, 2010). The parameter measuring effect size (θ_i) is a common metric that permits
145 direct comparison and summation of primary studies (Borestein et al., 2009).

146 $$\theta_i = logit\, p_i = ln\left(\frac{p_i}{1-p_i}\right) = ln\left(\frac{s_i}{n_i - s_i}\right) \quad (1)$$

147 Models with random-effects were used to calculate prevalence values (mean and 95% CI) of *L.*
148 *monocytogenes* across primary studies (Eq. 2; Borestein et al., 2009):

149 $$T_i = \theta_i + \varepsilon_i = \mu + u_i + \varepsilon_i \quad (2)$$

150 where T_i is the true effect size for each primary study (i = 1, 2, …), ε_i is the sampling error and μ is
151 the mean true effect size. u_i represents the true variation in effect sizes being compose of within-
152 study (σ^2) and between-study variance (τ^2).

153 The between-study variance (τ^2) is estimated from the Q-statistic (DerSimonian & Laird 1986),

$$\hat{\tau}^2 = \begin{cases} \frac{Q-(k-1)}{\sum w_i - \frac{\sum w_i^2}{\sum w_i}}, & for\ Q > (k-1) \\ 0, & for\ Q \leq (k-1) \end{cases} \quad (3)$$

where Q is calculated by Eq. 4 and 5, k is the number of studies and w_i the weight assigned to each study (Eq.5).

$$Q = \sum w_i (T_i - \mu)^2 \quad (4)$$

$$\mu = \frac{\sum_i w_i T_i}{\sum_i w_i} \quad (5)$$

$$w_i = \frac{1}{\sigma_i^2 + \tau_i^2} \quad (6)$$

A significant value of the Q-statistic indicates a real effect difference between primary studies and suggests the use of a multilevel model (Xabier et al., 2014). The I^2 index was used to measure the extent of between-study variance dividing the difference between the result of the Q-statistic and its degrees of freedom $(k-1)$ by the Q value itself, and then multiply by 100. Higgins & Thompson (2002) proposed a classification of I^2 values with percentages of around 25% ($I^2 = 25$), 50% ($I^2 = 50$) and 75% ($I^2 = 75$) corresponding to low, medium and high between-study variance, respectively. The τ^2 and I^2 indices are related and higher τ^2 values corresponds to higher I^2 index values.

Multilevel meta-analysis including type of cheese and pasteurized or unpasteurized milk were used to account for some of the observed between-study variance in prevalence data.

The multilevel models used were formulated as:

$$T_i = \beta_0 + \beta_1 X_{1i} + \cdots + \beta_k X_{ki} + u_i + \varepsilon_i \quad (7)$$

with $(X_1 to\ X_k)$ being study characteristics and β_k the moderator effects.

Meta-analysis modelling was performed by using R version 3.1.3 (R Development Core Team) and the "metafor" package (Viechtbauer, 2010), which provides functions for fitting of random-effects and multilevel models as well as meta-analytical graphs including forest plots.

2.6. Regression modelling

A linear regression model ($y = a + bx$) was used to evaluate the relation between prevalence of *Listeria* spp. (x) and prevalence of *L. monocytogenes* (y). Regression modelling was performed with R and an F-test was used to evaluate if the linear model could be reduced to $y = bx$.

3. Results

3.1. Meta-analysis of prevalence data from scientific literature

The overall prevalence for presence of *L. monocytogenes* in cheese was 2.3% (CI: 1.4-3.8%). Variability in reported prevalence among studies was high (Table 6 and Fig.1) and the between-study variance slightly decrease from $\tau^2 = 1.72$ to 1.12 when cheeses were grouped in categories by the multilevel model. Nevertheless, unexplained variability remained high ($I^2 = 75\%$; p-value < 0.001 in Table 6).

Fresh cheese had the lowest mean prevalence of 0.8% (CI: 0.3-1.9%), followed by ripened cheese 2.0% (CI: 0.8- 4.9%), veined cheese 2.4% (CI: 0.9- 6.3%) and smear cheese 5.1% (CI: 1.9-13.1%). Brined cheese had the highest *L. monocytogenes* prevalence of 11.8% (CI: 3.5-33.3%) (Table 6 and Fig. 1).

3.2. Meta-analysis of prevalence data from EFSA reports

193 The overall prevalence for presence of *L. monocytogenes* in cheese was 0.7% (CI: 0.5 –
194 1.1%) with high between-studies variance (Table 7). A multilevel model determined the prevalence
195 of *L. monocytogenes* in hard and soft/semi-soft cheeses produced from un-pasteurized or
196 pasteurized milk. No significant effect of pasteurization ($p > 0.05$) was observed within hard or
197 soft/semi-soft cheeses (Table 7).

198 A second random-effects meta-analysis was performed to assess non-compliance with the
199 criterion of 100 cfu/g for *L. monocytogenes* in ready-to-eat (RTE) foods. 0.2% (CI: 0.1-0.4) of the
200 cheese samples had more than 100 *L. monocytogenes*/g and high between-study variance was
201 observed (Table 8). Prevalence of *L. monocytogenes* in hard and soft/semi-soft cheese produced
202 with un-pasteurized or pasteurized milk was estimated. Pasteurization of milk had no significant
203 effect ($p > 0.05$) within hard or soft/semi-soft cheeses (Table 8).

204 *3.3. Meta-analysis of combined prevalence data from scientific literature and EFSA reports*

205 The overall prevalence of *L. monocytogenes* in European cheeses was 1.2% (CI: 0.8-1.8%).
206 High between-study variance was observed and a significant difference ($p < 0.001$) was determined
207 between data from the scientific literature and from EFSA reports data (Table 9).

208 *3.4. Evaluation of index organisms for prevalence of L. monocytogenes in European cheeses*

209 Of 3852 samples reporting presence of *Listeria* spp., 203 (5.3%) were positive for *L.*
210 *monocytogenes*, 327 (8.5%) *L. innocua*, 19 (0.5%) *L. grayi*, 188 (4.9%) *L. welshimer*, 18 (0.5%) *L.*
211 *ivanovii* and 20 (0.5%) *L. seeligeri*. The correlation factor was sufficient to describe the relation
212 between prevalence of *Listeria* spp. (x) and prevalence of *L. monocytogenes* (y) in cheeses ($y = 0.52$
213 x, $r^2 = 0.86$, Fig. 2).

214 **4. Discussion**

215 It is critical to understand and quantified prevalence of *L. monocytogenes* in cheeses since
216 they are an important vehicle for transmission of the pathogen and infection causes the highest
217 fatality case rate among zoonotic diseases (EFSA, 2016).

218 EU mean prevalence of *L. monocytogenes* in cheese from scientific literature exceeded what
219 was reported by EFSA for the same period. This may result from a focus on problematic cheese
220 products in scientific studies whereas EFSA reports include a larger number of samples from hard
221 cheeses where *L. monocytogenes* can be inactivated and prevalence therefore is lower. The data
222 from scientific studies corresponded to previous studies reporting prevalence between 0 and 4.8%
223 (Esho et al., 2013; Manfreda et al., 2005; Rosengren et al., 2010), but some other studies reported
224 more than 40% prevalence (Loncarevic et al., 1995; Pintado et al., 2005).

225 Mean prevalence of *L. monocytogenes* in fresh cheese was similar to the overall prevalence
226 obtained from EFSA data. In 1985 consumption of contaminated fresh cheese (queso blanco) was
227 directly linked to more than 142 cases of listeriosis, including 48 deaths (Linnan *et al*., 1988). From
228 2009 to 2012 there was an outbreak in Portugal linked to 30 cases of listeriosis, including 11 deaths
229 and related to consumption of fresh cheeses (curded cheese and queijo fresco) (Magalhães *et al.,*
230 2015). Furthermore, Greco et al., (2014) for example demonstrated how prevalence of *L.*
231 *monocytogenes* can be high (24.4%) in mozzarella cheese as result of cross-contamination.

232 Fresh cheeses were excluded from the EFSA baseline survey on prevalence of *L.*
233 *monocytogenes* in certain RTE foods within EU during 2010-2011 (EFSA, 2013a). Interestingly,
234 EFSA (2015) started to differentiate between fresh and soft/semi-soft cheeses but included only
235 2.1% fresh cheese samples compared to 80.1% hard cheese samples from a total of 13,718 cheese
236 samples. Hard cheese have never been linked to a listeriosis outbreak (Table 1) and as it does not
237 support growth of *L. monocytogenes* (Dalmasso & Jordan, 2014; Wemmenhove et al.,2013; Yousef

& Marth, 1990) the large number of these samples does not correspond to a risk-based sampling approach.

It is important to note that mean prevalence for brined cheese was estimated from only four studies with smaller sample sizes compare with other types of cheese. Consequently, there is a high level of uncertainty and results may be biased by results from a single study (Fig. 1; Table 6). In 2012, Ricotta salata imported from Italy and contaminated with *L. monocytogenes* was involved in a listeriosis outbreak in the USA with 22 hospitalizations and 4 deaths (CDC, 2012). Furthermore, ricotta salata supports growth of *L. monocytogenes* (Coroneo et al., 2016; Spanu et al., 2012) and production of this cheese includes manual processing of the curd and exposure to processing environments that increase the risk of *L. monocytogenes* contamination (Spanu et al., 2013). Our findings suggest that prevalence of *L. monocytogenes* in fresh and brined cheese are not negligible; therefore we encourage EFSA to increase and independently report sampling of fresh and brined cheeses since they have been related with listeriosis outbreaks recurrently (Table 1).

As shown by EFSA reports, contamination of cheese by *L. monocytogenes* is not specific to un-pasteurized milk cheeses since cheeses made from pasteurized milk can be contaminated due to inadequate pasteurization or post-pasteurization contamination (De Buyser et al., 2001; Donnelly, 2001). Our report is the first of our knowledge to analysed EFSA prevalence data of cheeses made from un-pasteurized and pasteurized milk. There was no significant difference in prevalence between cheeses produced with un-pasteurized or pasteurized milk; either for hard or soft/semi-soft cheeses (Table 7 and 8). This may be due to requirements leading to the use of milk of high microbiological quality for the production of un-pasteurized milk cheese and to post-pasteurization contamination of pasteurized milk cheese. Tiwari et al., (2015) compared the risk of soft/semi-soft cheese made from un-pasteurized or pasteurized milk and estimated a higher risk for un-pasteurized milk cheese as a consequence of the higher contamination rate of milk due to the lack of

pasteurization and growth of *L. monocytogenes* in un-pasteurized milk cheese but inactivation in the same pasteurized milk cheese. But this study observed no significant effect of pasteurization in prevalence of *L. monocytogenes* in soft/semi-soft cheese. We provide mean prevalence and distributions for *L. monocytogenes* in soft/semi-soft cheese that can be combined with concentration data of *L. monocytogenes* (cfu/g) for the same period in un-pasteurized and pasteurized milk cheese to perform a quantitative risk assessment of the end product (Crépet et al., 2007) and results from both studies could be compared.

Prevalence and concentration of *L. monocytogenes* in cheeses are low, hence evaluation of potential presence of other index or indicator microorganisms easier to determine or quantify was considered. *Listeria* spp. has been proposed as index organisms for presence of *L. monocytogenes* in RTE foods and as indicator of inadequate hygiene conditions in food production practices and environment (FSAI, 2011; Gilbert et al., 2000; McLauchlin, 1997). These findings were confirmed by the present study and we found prevalence of *L. monocytogenes* corresponded to prevalence of *Listeria* spp. when multiplied by a factor of 0.52. This was further supported by Trmčić et al., (2016) where 273 cheese samples had 12 positive for *Listeria* spp. and five of these positive for *L. monocytogenes*. Silva et al., (2003) also found 33% of *Listeria* spp. positive samples from cheese and dairy processing plants to be *L. monocytogenes* positive. However, Arrese & Arroyo-Izaga (2012) found no *L. monocytogenes* positive amongst 51 cheese samples with five samples positive for other *Listeria* spp. Microbiological methods for detection and quantification of *Listeria* spp. are not more performant than available methods for *L. monocytogenes* (Gasanov et al., 2005). Therefore, we do not consider *Listeria* spp. a useful index- or indicator-organism *L. monocytogenes* despite the relation reported in the present study (Fig. 2).

5. Conclusions

Meta-analysis provided pooled prevalence estimates for *L. monocytogenes* in specific types of cheeses, however, significant between-study variance was observed. Overall prevalence of *L. monocytogenes* in cheese as estimated from scientific literature data was higher than reported by data from EFSA during the same period 2005-2015. Considering prevalence of *L. monocytogenes* in cheeses produced with un-pasteurized or pasteurized milk no significant difference in prevalence was observed. The results obtained provided a broad picture of *L. monocytogenes* prevalence in cheeses and can be used as an important input in quantitative microbial risk assessments. *Listeria* spp. was not a useful index- or indicator-organism for *L. monocytogenes* in cheeses although prevalence of *Listeria* spp. was related to prevalence of *L. monocytogenes*.

Highlights:

- Overview of listeriosis outbreaks caused by cheese 1983-2016

- Overall prevalence of *L. monocytogenes* in European cheese 2005 - 2015

- Prevalence of *L. monocytogenes* in different types of cheese

- No indicator or index organism identified for *L. monocytogenes* in cheese
